Chapter 1

Introduction and Specifications

1.1 Project Overview

This laboratory report provides a comprehensive examination of the architecture, design, and implementation of a real-time video streaming application. The developed system operates on a standard client-server paradigm, leveraging the **Real-Time Streaming Protocol (RTSP)** for stateful control signaling over a reliable TCP connection, and the **Real-time Transfer Protocol (RTP)** for active media packetization and delivery.

The project addresses core challenges in multimedia communication over IP networks, specifically targeting robust performance and user experience. The key technical features implemented and discussed in this report include:

1. **Control Channel Signalling (RTSP):** The implementation of a structured, state-machine driven protocol for session control (inclusive of SETUP, PLAY, PAUSE, and TEARDOWN routines).
2. **High-Concurrency I/O Multiplexing:** The server architecture has been modernized using a single-threaded, high-performance event loop utilizing Python's selectors module, replacing the traditional thread-per-client model.
3. **Media Delivery (RTP):** The encapsulation of Motion JPEG (MJPEG) frames into standard RTP packets with a compliant 12-byte binary header (including version, payload type, sequence numbers, timestamps, marker bits, and SSRC).
4. **UDP Packet Fragmentation:** A robust mechanism for chunking large video frames that exceed the Maximum Transmission Unit (MTU) into multiple RTP sub-packets, with marker-bit-based reassembly on the client.
5. **Reliable TCP Transport Mode:** The introduction of **RTP-over-TCP** streaming. To prevent TCP byte-stream amalgamation, a custom 5-byte frame size header mechanism was engineered, facilitating stable, frame-by-frame transmission without packet loss or sequence reordering.
6. **Adaptive Quality Switching with Client-Side Caching:** The development of a dynamic quality toggle (SD ↔ HD) within the client interface. The client maps SD to UDP transport and HD to TCP transport. A client-side frame buffer with a high/low water mark mechanism reduces jitter during playback, and a draining pipeline ensures seamless transitions when the user triggers a "Setup Again" to reset the stream.

1.2 Group Members and Task Allocation

The project was executed collaboratively by the following team members. Both members contributed extensively to the research, design, implementation, and testing phases.

Full Name	Student ID	Email
Đặng Võ Hồng Phúc	23120155	23120155@student.hcmus.edu.vn
Trịnh Chấn Duy	23120419	23120419@student.hcmus.edu.vn

1.2.1 Work Division

The technical workload was distributed as follows to ensure cross-functional understanding of the entire codebase:

Assigned Tasks	Assigned Members
RTSP Client GUI and internal state-machine implementation	All Members
RTP Packetization, V/P/X/CC/PT/SSRC header encoding	All Members
UDP fragmentation and marker-bit chunk reassembly logic	All Members
Server conversion to I/O Multiplexing event loop (selectors)	All Members
TCP transport option and 5-byte length-prefix framing	All Members
Client-side jitter buffer with high/low water marks	All Members
Setup Again draining pipeline and quality re-negotiation	All Members
System verification, testing, and English report writing	All Members

Chapter 2

System Architecture and Protocol Design

2.1 RTSP State Machine and Control Signalling

The Real-Time Streaming Protocol (RTSP) functions as a stateful, out-of-band control protocol. In our implementation, RTSP operates over a reliable TCP channel (binding to an administrator-defined port). The RTSP protocol is responsible for establishing and modifying media sessions through three sequential states: INIT, READY, and PLAYING.

Figure 2.1: RTSP Session Control State Machine

The text-based RTSP protocol requires strict header parsing. The CSeq (Command Sequence Number) is incremented by one for each sequential request to maintain synchronization. The Session header maintains the transaction binding between the client and server throughout the lifecycle of a streaming session.

2.1.1 Extended SETUP for Transport Negotiation

Our system extends the standard SETUP request to dynamically negotiate the transport protocol. The client determines the transport based on the selected quality: selecting **SD** maps to RTP/UDP, while selecting **HD** maps to RTP/TCP. The Transport header is the sole mechanism for this negotiation — the server reads only this header to determine whether to stream via UDP or TCP:

```
1 SETUP movie.Mjpeg RTSP/1.0
2 CSeq: 1
3 Transport: RTP/TCP; client_port= 25000
```

Listing 2.1: RTSP SETUP request with Transport negotiation

2.1.2 Re-SETUP for Quality Switching

A distinctive feature of our implementation is that the server accepts SETUP requests from **any state**, not just INIT. When a SETUP arrives while the server is in PLAYING state, it gracefully stops the current sending thread, closes the existing RTP socket, creates a fresh VideoStream (resetting to frame 0), and transitions back to READY. This enables seamless quality switching without full session teardown.

2.2 RTP Packetization and UDP Fragmentation

The RTP protocol encapsulates video payloads with a standard 12-byte binary header. When utilizing UDP as the underlying transport mechanism, the payload size is strictly constrained by the network's Maximum Transmission Unit (MTU). Standard Ethernet MTU is 1500 bytes. Deducting the IP header (20 bytes) and the UDP header (8 bytes) yields a maximum UDP payload of 1472 bytes. Deducting the 12-byte RTP header gives a maximum safe video payload of 1460 bytes. We conservatively selected **1400 bytes** as our maximum chunk size (MAX_RTP_PAYLOAD_SIZE).

Since a single MJPEG frame often exceeds this limit (sometimes reaching 6–10 KB), we engineered a fragmentation algorithm:

1. **MTU Fragmentation:** If a raw MJPEG frame exceeds 1400 bytes, the server slices the byte-array into N consecutive chunks using a `while bytesSent < frameSize` loop.
2. **Marker Bit (M):** The RTP marker bit (bit 8 in the second header byte) plays a crucial role. It is set to 0 for intermediate chunks and 1 exclusively for the final chunk of a given frame. This is computed dynamically as `(bytesSent + chunkSize) == frameSize`.
3. **Sequence Numbers:** The RTP sequence number (`rtpSeq`) is incremented for each individual fragment chunk, not just per frame. This allows the client to identify lost or out-of-order packets at the chunk level.
4. **Client Reassembly:** The client constantly reads UDP datagrams, decodes the RTP header, extracts sequence numbers, and appends payloads into a RAM buffer. Upon receiving a packet with a marker bit of 1, the client flushes the buffer, joins the segments into a complete JPEG image, and enqueues it into the frame buffer.

2.3 Reliable Frame-by-Frame TCP Media Stream

While UDP is suitable for low-latency, loss-tolerant streams, high-definition (HD) video demands absolute reliability. Over UDP, a single lost chunk corrupts the entire reassembled frame, resulting in visual artifacts. To resolve this, we implemented an **RTP-over-TCP** media stream.

The Framing Problem: TCP is a stream-oriented protocol. It guarantees delivery and order but does not preserve message boundaries. If the server sends two 5KB frames back-to-back, the client's `recv()` call might read parts of both frames simultaneously, completely corrupting the JPEG decoding process.

The Solution: We engineered a custom framing protocol. Before transmitting a frame, the server calculates its exact byte length and prepends this length as a **5-byte zero-padded ASCII string** (e.g., "06742"). The client reads exactly 5 bytes from the socket to determine the payload size, then invokes a specialized `recv_all(length)` function to extract exactly that many bytes. This completely bypasses the fragmentation and sequence tracking overhead of UDP, delivering each frame as a single, intact unit.

2.3.1 TCP Connection Establishment

For TCP media delivery, the roles are reversed compared to the control channel: the **client** acts as the TCP listener (`socket.listen(1)`) on the RTP port, and the **server** connects to the client after receiving a PLAY request. The client uses `SO_REUSEADDR` to allow rapid port rebinding when switching quality.

2.4 Client-Side Caching and Jitter Buffer

The client-side caching mechanism implements a **producer-consumer** architecture with a shared frame buffer to decouple network I/O from GUI rendering:

1. **Producer (Network Thread):** The `listenRtpWithUDP` or `listenRtpWithTCP` method runs in a background thread. Instead of directly updating the GUI, it appends complete frames into a shared `frameBuffer` list (capacity: 100 frames), protected by a `threading.Lock` (`bufferLock`).
2. **Consumer (GUI Render Loop):** The `renderClientBufferLoop` method is scheduled via Tkinter's `master.after()` mechanism. It pops frames from the buffer at a fixed cadence (every 40ms, approximately 25 fps) and calls `updateMovie()` to render each frame.
3. **High Water Mark:** When the buffer is empty and new playback begins, the consumer enters a **buffering** state (`isBuffering = True`). It waits until the buffer accumulates at least `minBufferSize` (15) frames before beginning to render. This pre-buffering absorbs network jitter and provides a smooth initial playback experience.
4. **Low Water Mark / Starvation Recovery:** If the buffer drains to zero during normal playback (`len(frameBuffer) == 0`), the consumer re-enters the buffering state and waits for the high water mark to be reached again.

2.5 Setup Again: Draining Pipeline and Stream Reset

The “Setup Again” feature allows the user to click the Setup button at any point during playback or pause to reset the video stream and choose a new quality. The implementation uses a **draining pipeline** to ensure a graceful transition:

1. **During PLAYING state:** When the user clicks Setup, the system sets `pendingSetup = True` and calls `startDrainingPipeline()`. This signals the network thread to stop (`playEvent.set()`) and sets `isDraining = True`. The render loop continues to pop and display remaining buffered frames.
2. **Buffer Drain:** The `renderClientBufferLoop` detects `isDraining == True` and skips the buffering check, directly consuming frames until the buffer is empty.
3. **Transition:** Once the buffer is fully drained, the render loop checks `pendingSetup`. If true, it resets the client state to `INIT` and triggers `chooseQuality()` to display the quality selection dialog.
4. **During READY (Paused) state:** The buffer is cleared immediately, state resets to `INIT`, and the quality dialog appears instantly.
5. **Server Re-SETUP:** On the server side, the `SETUP` handler cleans up any previous session resources (stops old sending thread, closes old RTP socket) and creates a fresh `VideoStream` from the beginning. The session ID is preserved to avoid breaking the RTSP control channel.

Chapter 3

Code Implementation Details

This chapter provides an in-depth analysis of the source code, highlighting the advanced features implemented to meet the project's specifications.

3.1 High-Performance Server I/O Multiplexing

Spawning a separate thread for every connected client is inefficient, leading to context-switching overhead and poor scalability. To support high-concurrency client streams, we refactored `Server.py` to utilize **I/O Multiplexing** via Python's `selectors` module.

```
1 class Server:
2     def __init__(self):
3         self.serverWorkers = {}
4         self.selectors = selectors.DefaultSelector()
5
6     def accept_client(self, rtspSocket):
7         try:
8             clientSocket, clientAddress = rtspSocket.accept()
9             clientSocket.setblocking(False) # Critical: Non-blocking mode
10            clientInfo = {'rtspSocket': (clientSocket, clientAddress)}
11
12            worker = ServerWorker(clientInfo)
13            self.serverWorkers[clientSocket] = worker
14            # Register the new client socket for read events
15            self.selectors.register(clientSocket, selectors.EVENT_READ,
16                                   self.handle_client_request)
17
18        except Exception as e:
19            print(f"Error accepting client: {e}")
20
21    def handle_client_request(self, clientSocket):
22        worker = self.serverWorkers.get(clientSocket)
23        if worker:
24            try:
25                worker.recvRtspRequest()
26            except Exception as e:
27                print(f"Cleaning up disconnected client: {e}")
28                try:
29                    self.selectors.unregister(clientSocket)
30                except:
31                    pass
32                clientSocket.close()
33                if clientSocket in self.serverWorkers:
34                    del self.serverWorkers[clientSocket]
```

```
34
35 def main(self):
36     rtspSocket = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
37     rtspSocket.bind(('', SERVER_PORT))
38     rtspSocket.listen(5)
39     rtspSocket.setblocking(False)
40     self.selectors.register(rtspSocket, selectors.EVENT_READ,
41                             self.accept_client)
42
43     # The Event Loop
44     while True:
45         events = self.selectors.select()
46         for key, mask in events:
47             callback = key.data
48             callback(key.fileobj)
```

Listing 3.1: Server.py - Non-blocking Event Loop

The server socket and all incoming client sockets are explicitly set to non-blocking mode (`setblocking(False)`). The primary server loop halts at `self.selectors.select()`, waiting for OS-level interrupts indicating readable events. When data arrives, it dispatches the RTSP commands to the appropriate `ServerWorker` without launching redundant threads.

3.1.1 Non-blocking Socket and BlockingIOError Handling

Because all client sockets operate in non-blocking mode, the `recvRtspRequest` method in `ServerWorker.py` must handle `BlockingIOError`, which is raised when `recv()` is called on a non-blocking socket with an empty kernel buffer. The exception is silently caught and the method returns, allowing the event loop to continue monitoring other sockets:

```
1 def recvRtspRequest(self):
2     connSocket = self.clientInfo['rtspSocket'][0]
3     try:
4         while True:
5             data = connSocket.recv(256)
6             if data:
7                 self.processRtspRequest(data.decode("utf-8"))
8             else:
9                 raise ConnectionError("Client disconnected")
10    except BlockingIOError:
11        pass # No data available yet, return to event loop
```

Listing 3.2: ServerWorker.py - Non-blocking RTSP Reception

3.1.2 Graceful Client Disconnection Cleanup

When a client disconnects (detected by `recv()` returning empty bytes or raising a `ConnectionError`), the exception propagates to `handle_client_request` in `Server.py`, which performs cleanup: unregistering the socket from the selector, closing the socket, and removing the worker from the dictionary. This prevents stale file descriptors from accumulating.

3.2 RTP Packetization and Binary Header Encoding

The `RtpPacket.py` module implements the standard 12-byte RTP header encoding according to RFC 1889:

```

1 def encode(self, version, padding, extension, cc, seqnum,
2     marker, pt, ssrc, payload):
3     timestamp = int(time())
4     header = bytearray(HEADER_SIZE)
5
6     # Byte 0: V(2) | P(1) | X(1) | CC(4)
7     header[0] = (version << 6) | (padding << 5) | \
8         (extension << 4) | (cc & 0x0F)
9     # Byte 1: M(1) | PT(7)
10    header[1] = (marker << 7) | (pt & 0x7F)
11    # Bytes 2-3: Sequence Number (16-bit, big-endian)
12    header[2] = (seqnum >> 8) & 0xFF
13    header[3] = seqnum & 0xFF
14    # Bytes 4-7: Timestamp (32-bit, big-endian)
15    header[4] = (timestamp >> 24) & 0xFF
16    header[5] = (timestamp >> 16) & 0xFF
17    header[6] = (timestamp >> 8) & 0xFF
18    header[7] = timestamp & 0xFF
19    # Bytes 8-11: SSRC (32-bit, big-endian)
20    header[8] = (ssrc >> 24) & 0xFF
21    header[9] = (ssrc >> 16) & 0xFF
22    header[10] = (ssrc >> 8) & 0xFF
23    header[11] = ssrc & 0xFF
24
25    self.header = header
26    self.payload = payload

```

Listing 3.3: RtpPacket.py - 12-byte RTP Header Encoding

The header fields are filled byte-by-byte using bitwise shift and mask operations. Since Python's byte order matches network byte order (big-endian), no additional byte-order transformation is required. The decode method performs the reverse: extracting the 12-byte header and payload from a received byte stream, with accessor methods for `version()`, `seqNum()`, `marker()`, `timestamp()`, and `payloadType()`.

3.3 UDP Fragmentation Logic

The `ServerWorker.py` script manages the fragmentation of large JPEG frames to fit within the UDP MTU constraints:

```

1 def sendRtpWithUDP(self):
2     MAX_RTP_PAYLOAD_SIZE = 1400
3     while True:
4         self.clientInfo['event'].wait(0.05)
5         if self.clientInfo['event'].isSet():
6             break
7
8         data = self.clientInfo['videoStream'].nextFrame()
9         if data:
10            frameSize = len(data)
11            bytesSent = 0
12            while bytesSent < frameSize:
13                chunkSize = min(MAX_RTP_PAYLOAD_SIZE,
14                    frameSize - bytesSent)
15                chunkData = data[bytesSent:bytesSent + chunkSize]
16                # Marker bit = 1 ONLY for the final chunk
17                markerBit = (bytesSent + chunkSize) == frameSize
18
19                packet = self.makeRtp(chunkData, self.rtpSeq,

```

```

20                                     markerBit)
21         self.clientInfo['rtpSocket'].sendto(
22             packet, (address, port))
23
24         self.rtpSeq += 1
25         bytesSent += chunkSize

```

Listing 3.4: ServerWorker.py - UDP Fragmentation with Marker Bit

The while `bytesSent < frameSize` loop slices the byte array into chunks of at most 1400 bytes. The `markerBit` is computed dynamically by checking if the current chunk boundary aligns with the total `frameSize`. This ensures the client can detect frame boundaries even when a single frame is split across many UDP datagrams.

3.3.1 Client-Side UDP Reassembly

On the client side, fragments are reassembled using a temporary buffer that accumulates chunk payloads until the marker bit signals the end of a frame:

```

1 def listenRtpWithUDP(self):
2     buffer = []
3     while not self.playEvent.isSet():
4         try:
5             data = self.rtpSocket.recv(2000)
6             if data:
7                 rtpPacket = RtpPacket()
8                 rtpPacket.decode(data)
9                 currSeqNbr = rtpPacket.seqNum()
10
11                 if currSeqNbr > self.frameNbr:
12                     self.frameNbr = currSeqNbr
13                     buffer.append(rtpPacket.getPayload())
14
15                 if rtpPacket.marker() == 1:
16                     fullFrame = b''.join(buffer)
17                     buffer.clear()
18                     with self.bufferLock:
19                         self.frameBuffer.append(fullFrame)
20                         if len(self.frameBuffer) > 100:
21                             self.frameBuffer.pop(0)
22         except:
23             buffer.clear()
24             if self.playEvent.isSet(): break

```

Listing 3.5: Client.py - UDP Fragment Reassembly

Late or out-of-order packets are discarded via the `currSeqNbr > self.frameNbr` guard. Once the marker bit is detected (`marker() == 1`), the accumulated chunks are joined with `b''.join(buffer)` and appended to the shared `frameBuffer` under lock protection. A hard cap of 100 frames prevents unbounded memory growth.

3.4 Reliable TCP Stream Framing Protocol

To circumvent TCP's inherent byte-stream nature, we engineered a custom 5-byte length prefix system.

3.4.1 Server-side Transmission

```

1 def sendRtpWithTCP(self):
2     while True:
3         self.clientInfo['event'].wait(0.05)
4         if self.clientInfo['event'].isSet():
5             break
6
7         data = self.clientInfo['videoStream'].nextFrame()
8         if data:
9             frameSize = len(data)
10            # 5-byte ASCII size header, zero-padded (e.g. "06742")
11            sizeHeader = str(frameSize).zfill(5).encode()
12            # Send header + payload atomically
13            self.clientInfo['rtpSocket'].sendall(sizeHeader + data)

```

Listing 3.6: ServerWorker.py - TCP 5-byte Length-Prefix Framing

3.4.2 Client-side Reception

On the client side, Client.py employs a strict `recv_all` loop to guarantee no partial reads occur:

```

1 def listenRtpWithTCP(self):
2     # Client listens; server connects after PLAY
3     self.rtpSocket.settimeout(5.0)
4     self.rtpConnection, addr = self.rtpSocket.accept()
5     self.rtpConnection.settimeout(0.5)
6
7     while not self.playEvent.isSet():
8         # Read exactly 5 bytes for the length prefix
9         length_bytes = self.recv_all(self.rtpConnection, 5)
10        if not length_bytes: break
11
12        length = int(length_bytes.decode())
13        data = self.recv_all(self.rtpConnection, length)
14        if not data: break
15
16        with self.bufferLock:
17            self.frameBuffer.append(data)
18            if len(self.frameBuffer) > 100:
19                self.frameBuffer.pop(0)
20
21 def recv_all(self, sock, n):
22     """Receive exactly n bytes from a TCP socket."""
23     data = b''
24     while len(data) < n:
25         try:
26             packet = sock.recv(n - len(data))
27             if not packet:
28                 return None
29             data += packet
30         except socket.timeout:
31             if len(data) > 0:
32                 continue
33             else:
34                 raise
35     return data

```

Listing 3.7: Client.py - Precise TCP Reception with `recv_all`

The `recv_all` function loops until exactly n bytes have been received. Socket timeouts are handled gracefully: if a partial read has already occurred, the function continues waiting; otherwise, it re-raises the timeout to allow the outer loop to check for `playEvent`.

3.5 Client-Side Jitter Buffer and Render Loop

The render loop is the heart of the client-side caching system, implementing the consumer side of the producer-consumer pattern:

```

1 def renderClientBufferLoop(self):
2     if self.state != self.PLAYING and not self.isDraining:
3         return
4
5     with self.bufferLock:
6         # High Water Mark: wait for minBufferSize frames
7         if self.isBuffering and not self.isDraining:
8             if len(self.frameBuffer) >= self.minBufferSize:
9                 self.isBuffering = False
10            else:
11                self.master.after(40, self.renderClientBufferLoop)
12                return
13
14        if len(self.frameBuffer) > 0:
15            frame_bytes = self.frameBuffer.pop(0)
16            self.updateMovie(self.writeFrame(frame_bytes))
17        else:
18            if self.isDraining:
19                # Buffer fully drained
20                self.isDraining = False
21                self.state = self.INIT
22                self.frameNbr = -1
23                if self.pendingPause:
24                    self.pendingPause = False
25                    self.state = self.READY
26                elif self.pendingSetup:
27                    self.pendingSetup = False
28                    self.state = self.INIT
29                    self.chooseQuality()
30                return
31            else:
32                # Starvation: re-enter buffering
33                self.isBuffering = True
34
35        # Schedule next frame render (~25fps)
36        self.master.after(40, self.renderClientBufferLoop)

```

Listing 3.8: Client.py - `renderClientBufferLoop` (Jitter Buffer Consumer)

Key design decisions:

- The render loop uses `master.after()` (Tkinter's non-blocking timer) instead of a separate thread. This ensures all GUI updates occur on the main thread, avoiding Tkinter's well-known thread-safety issues.
- The `bufferLock` mutex protects the shared `frameBuffer` list from concurrent access by the network producer thread.
- The draining pipeline integrates naturally: when `isDraining` is true, the buffering check is bypassed, and the loop pops frames until the buffer is empty.

3.6 Setup Again: Server-Side Re-SETUP Handler

The server's `processRtspRequest` method was extended to accept SETUP from any state, enabling mid-session quality switching:

```

1 if requestType == self.SETUP:
2     # Clean up previous session resources if they exist
3     if 'event' in self.clientInfo and self.clientInfo['event']:
4         try: self.clientInfo['event'].set()
5         except: pass
6     if 'worker' in self.clientInfo and self.clientInfo['worker']:
7         try: self.clientInfo['worker'].join(timeout=0.2)
8         except: pass
9     if 'rtspSocket' in self.clientInfo and self.clientInfo['rtspSocket']:
10        try: self.clientInfo['rtspSocket'].close()
11        except: pass
12
13    # Create fresh VideoStream (resets to frame 0)
14    self.clientInfo['videoStream'] = VideoStream(filename)
15    self.state = self.READY
16    self.rtpSeq = 0
17
18    # Preserve session ID for RTSP control channel continuity
19    if self.clientInfo.get('session') is None:
20        self.clientInfo['session'] = randint(100000, 999999)
21
22    self.replyRtsp(self.OK_200, seq[1])
23
24    # Parse Transport header (UDP or TCP)
25    transport_line = request[2]
26    self.clientInfo['transport'] = 'UDP'
27    if 'TCP' in transport_line:
28        self.clientInfo['transport'] = 'TCP'

```

Listing 3.9: ServerWorker.py - Re-SETUP Handler for Quality Switching

The handler first checks for and cleans up any existing session resources (event, worker thread, RTP socket). It then creates a fresh `VideoStream`, resetting playback to frame 0. The session ID is preserved (only generated on the first SETUP) to maintain RTSP control channel continuity.

3.7 Client-Side Quality Selection UI

The client presents a styled modal dialog for quality selection, built with Tkinter:

```

1 def chooseQuality(self):
2     self.quality_window = Toplevel(self.master)
3     self.quality_window.title("Video Quality")
4     self.quality_window.configure(bg="#1E1E1E")
5
6     self.quality_var = StringVar(value="SD")
7
8     rb_sd = Radiobutton(frame, text="SD (720p) - UDP",
9                         variable=self.quality_var, value="SD", ...)
10    rb_hd = Radiobutton(frame, text="HD (1080p) - TCP",
11                        variable=self.quality_var, value="HD", ...)
12
13    # Modal behavior
14    self.quality_window.transient(self.master)
15    self.quality_window.grab_set()

```

```
16     self.master.wait_window(self.quality_window)
17
18 def confirmQuality(self):
19     self.quality = self.quality_var.get()
20     if self.quality == "HD":
21         self.transport = "TCP"
22     else:
23         self.transport = "UDP"
24     self.quality_window.destroy()
25     self.sendRtspRequest(self.SETUP)
```

Listing 3.10: Client.py - Quality Selection Dialog

The mapping is straightforward: SD (720p) uses UDP for low-latency delivery, while HD (1080p) uses TCP for reliable, lossless transmission. The dialog is modal (`grab_set()` and `wait_window()`), ensuring the user must make a selection before proceeding.

Chapter 4

Verification and Experimental Results

4.1 UDP Mode and MTU Fragmentation Tests

We rigorously tested the application under UDP mode. When streaming large frames, the server successfully identifies payloads exceeding 1400 bytes and splits them, sending consecutive RTP packets with incrementing sequence numbers. The client output verifies successful reassembly:

```
1 Current Seq Num: 774
2 Size of packet: 1412
3 Current Seq Num: 775
4 Size of packet: 1412
5 Current Seq Num: 776
6 Size of packet: 1173
```

Listing 4.1: Client-side terminal output showing UDP fragmentation

This log demonstrates that a single frame of approximately 3985 payload bytes was successfully fragmented into two maximal chunks of 1400 payload bytes (plus 12 bytes RTP header, totalling 1412 bytes per packet) and a final chunk of 1161 payload bytes. The marker bit on the third packet triggered the client's buffer join, producing a valid JPEG that rendered correctly in the GUI.

4.2 TCP Mode and Frame-by-Frame Delivery

When TCP mode is selected via the quality dialog (HD option), the server connects to the client's listening socket and delivers frames with the 5-byte ASCII headers. Terminal output verifies the handshake and data integrity:

```
1 Data sent:
2 SETUP movie.Mjpeg RTSP/1.0
3 CSeq: 1
4 Transport: RTP/TCP; client_port= 25000
5
6 Received RTSP reply: RTSP/1.0 200 OK
7 CSeq: 1
8 Session: 728783
9
10 RTP/TCP socket listening on port 25000
11 RTP/TCP connection established with server
12
13 Received Frame over TCP
14 Size of packet: 6014
15 Received Frame over TCP
16 Size of packet: 5940
```

```
17 Received Frame over TCP
18 Size of packet: 5925
```

Listing 4.2: RTSP Setup and TCP Stream verification

Each frame is delivered as an uninterrupted single unit without any chunk splits. The `sendall()` call on the server and the strict `recv_all()` loop on the client ensure complete, corruption-free frame delivery. No packet loss or visual tearing was observed during TCP streams.

4.3 Client-Side Jitter Buffer Verification

The jitter buffer was tested under the following scenarios:

- **Initial Buffering:** When the user clicks “Play”, the render loop enters the buffering state. The console shows the buffer filling up to 15 frames before playback begins, providing a smooth startup experience with no initial stutter.
- **Starvation Recovery:** By artificially delaying the server’s sending rate, we observed the buffer draining to zero, the client re-entering the buffering state, and playback resuming smoothly after 15 frames accumulated again.
- **Buffer Overflow Protection:** The 100-frame hard cap prevents memory exhaustion. When the producer outruns the consumer, the oldest frame is discarded (`pop(0)`).

4.4 Setup Again / Quality Switch Verification

The “Setup Again” feature was tested in multiple scenarios:

- **Switch During Playback:** While playing in SD/UDP, clicking Setup triggers the draining pipeline. The video continues playing from the buffer (visible for several frames), then the quality dialog appears. Selecting HD and clicking Play starts the video from frame 0 over TCP.
- **Switch During Pause:** While paused, clicking Setup immediately clears the buffer and shows the quality dialog. No draining is needed since no frames are being rendered.
- **Server Resource Cleanup:** Server logs confirm that the old sending thread is stopped, the old RTP socket is closed, and a fresh `VideoStream` is created upon re-SETUP. No resource leaks were observed.

4.5 I/O Multiplexing Scalability

The `selectors`-based server was tested with multiple simultaneous clients. The single-threaded event loop correctly dispatched RTSP commands to the appropriate `ServerWorker` instances. Client disconnections were detected and cleaned up gracefully (selector unregistration, socket closure, worker dictionary removal).

Chapter 5

Conclusion

We have successfully implemented a fully functional RTSP/RTP video streaming application that addresses all requirements outlined in the project specification. This project went beyond basic functional requirements by incorporating advanced networking concepts. The key accomplishments are summarized below:

1. **RTSP/RTP Control & Packetization:** Complete state-machine management for SETUP, PLAY, PAUSE, and TEARDOWN operations. Robust 12-byte RTP header encoding with proper version, payload type, sequence number, timestamp, marker bit, and SSRC fields. MTU-aware UDP fragmentation with marker-bit-based client-side reassembly (4/4 Points).
2. **I/O Multiplexing:** Modernized, single-threaded, event-driven server loop via Python's selectors module. Non-blocking sockets with proper BlockingIOError handling and graceful client disconnection cleanup (1/1 Point).
3. **HD Video Streaming over TCP:** Flawless frame-by-frame TCP transfer leveraging a custom 5-byte zero-padded ASCII size header. The `recv_all()` helper guarantees complete frame reception regardless of TCP segmentation. Client-driven quality selection maps SD to UDP and HD to TCP transport (2/2 Points).
4. **Client-Side Caching and Quality Switch:** Thread-safe producer-consumer jitter buffer with high/low water mark buffering (15-frame threshold). Tkinter `after()`-based render loop for thread-safe GUI updates. Draining pipeline for graceful "Setup Again" transitions. Server-side re-SETUP handler that resets `VideoStream` to frame 0 while preserving the RTSP session (2.5/2.5 Points).
5. **English Technical Report:** Fully compiled, comprehensive document with deep code analysis and experimental verification (0.5/0.5 Point).

Through this rigorous laboratory exercise, our team gained practical knowledge in network socket programming, byte-level packet manipulation, thread-safe asynchronous GUI development, I/O multiplexing, and adaptive multimedia streaming protocol design.
